1. Introduction

S. Rao Kosaraju [2] in considering the question of how one can sort on parallel machines was lead to consider parallel machines that are organized into  $n \times n$  arrays, i.e., configurations where the  $(i,j)$ th machine can communicate only with the machines  $(i+1,j)$ ,  $(i-1,j)$ ,  $(i,j+1)$ , and  $(i,j-1)$ . The question is, of course, not whether such arrays can sort but rather how fast they can sort. In particular, Kosaraju was lead to a specific simple set of rules for the behavior of the machines and then conjectured that for these rules sorting required at most  $O(n)$  time. Our principle result, however, is the failure of this conjecture. Indeed, we will demonstrate that Kosaraju's rules require in worst case at least  $cn^2$  ( $c > 0$  constant) time.

The fact that Kosaraju's rules fail to sort in  $O(n)$  time leads us to consider the general question: are all "local" rules (in a reasonable sense) unable to sort in  $O(n)$  time; indeed, do all such rules require at least  $cn^2$  time in worst case. The evidence that we have to support this conjecture is a series of rules similar to Kosaraju's that all have worst case sorting times of  $cn^2$ . On the other hand, it is known (Thompson [3]) that there are arrays that can sort in  $O(n)$  time. However, these arrays use quite nonlocal rules; hence, they do not contradict our conjecture but instead serve to help delimit the notion of local.

The motivation for studying Kosaraju's conjecture is twofold. First, the question of whether or not a local set of rules can sort in  $O(n)$  time is an interesting problem. Second, if there is a set of local rules that can sort in  $O(n)$  time, then it may be possible to build hardware that implements directly such an array.

Finally, a note about the organization of the rest of the paper. In section 2 we will present Kosaraju rules and then prove in section 3 that these rules require  $cn^2$  time in worst case. In section 4 we will sketch several other systems of rules with the same worst case behavior.

2. The Kosaraju Rules

We will now define the set of rules that Kosaraju had considered. As in Knuth [1], we consider arrays of 0's and 1's rather than arrays of arbitrary numbers.

Kosaraju Rules:

- (1) *Bubble:* If a 0 appears directly above a 1, interchange the 0 and 1.
- (2) *Snake:* If a 0 appears directly in front of a 1 in a "snake order" on the array, and rule (1) does not apply to this 0 or 1, then interchange the 0 and 1.

Letting  $(i,j)$  represent the row  $i$ , column  $j$  cell of the array, the "snake order" is

$(1,1)(1,2)\dots(1,n)(2,n)(2,n-1)\dots$   
 $(2,1)(3,1)(3,2)\dots(3,n)$

ending in  $(n,n)$  for  $n$  odd and  $(n,1)$  for  $n$  even. This is shown for  $n=4$  and  $n=5$  in Figure 1.

Figure 1: Snake order on boards of  $n=4$  and  $n=5$ .

A step in the sorting process is from the current configuration of 0's and 1's to a new configuration in which *all* interchanges allowed by the rules applied to the current configuration actually occur. Thus, the process does

many simultaneous interchanges. The time required by these rules is then the number of such parallel steps until no rules are applicable.

3. The Lower Bound for the Kosaraju Rules

**Theorem:** There exists an  $n \times n$  binary array requiring  $cn^2$  ( $c > 0$ ) time to sort using the Kosaraju sorting rule.

**Proof:**

Assume:  $n = 4k+3$   $k \in \mathbb{N}^+$   
 $k = (n-1)/2$

The array has the form

Define the fields of the array as follows:

**Fact 1:** The sizes and initial states of the fields are as follows:

- Source = all 1's =  $2 \times k$
- target = all 0's =  $2 \times k$
- $A_1$  = all 1's =  $k-1 \times 1$
- $B_1$  = all 0's =  $k-2 \times 1$
- FF =  $\langle 2, 0 \rangle = 1 \times 2$  at coordinates  $(k+1, k+1)(k+1, k+2)$
- $A_2$  = all 1's =  $k \times 1$
- $B_2$  = all 0's =  $k-1 \times 1$
- I = all 1's
- 0 = all 0's

**Fact 2:** The directionality of the fields is

The structure of the computation may be divided into the following pieces:

Steps #1 & #2	Steps
Preamble	$a_1 = 2$
$\lambda$ -Iterations	$a_2$
Conclusions	$a_3$
	$a_4$

(the time analysis will be given later).

**Overview of behavior:** We will claim that the source field emits 1's at a uniform rate, that they move up the  $A_2$  channel at the same rate to the "1/2 way" point, F, cross over (smoothly) to the  $B_1$  channel, proceed up this channel and are absorbed by the target in a smooth rate. When the source is exhausted, then the two row field above it will be the next source field and that it enters the computation smoothly. When the target fills, the next two row field beneath it becomes the new target and that it does so smoothly. Meanwhile, the I (0) field will remain constant 1's (0's). Finally, during the iteration steps the  $A_1$  field ( $B_2$  field) will be constant 1's (0's).

**Definition:** A field is said to *uniformly emit ones* (ueo) if it delivers a 1 to a fixed cell of the field on alternating steps until it is exhausted.

A field is said to *uniformly absorb ones* (uao) if it accepts 1's from a fixed cell of the field on alternating steps until it is filled.

**Remark:** The stronger property will be used that ueo's emit 1's only originally in the field and uao's will store the 1's only within the field.

A field is said to *uniformly transmit ones* if it moves 1's from a fixed cell to a fixed cell such that 1's are absorbed (emitted) on alternating steps.

**Fact 2:** The first step of the computation is:

Note the configuration of TARGET is the basis step in the following lemma.

**Lemma 1:** Target uniformly absorbs ones provided 1's are uniformly emitted from  $B_1$ .

*Proof:*

Using directionality (Fact 2), argue in two steps each by induction.

Step 1: fill top

hypothesis

↓ alternating

↓

↓

Step 2: fill bottom

hypothesis from Step 1 completion

alternating

use Floyd [1]

□

Denote the left and right halves of  $F$  as  $F_a$  and  $F_b$ . Call  $B$  the column  $B_1 B_2$ .

*Lemma 2:* During steps 2 through  $k$ ,  $B$  ueo from its top position.

*Proof:*

Since 1's in  $B$  have a 0 in them the Kosaraju move takes precedence. By Lemma 1, target can absorb the 1's uniformly so the alternating sequence isn't broken. □

*Remark:*  $B$  actually emits all 1's currently in  $B$  at step 1 by this argument, but we are only concerned with the preamble moves.

*Lemma 3:* During steps 2 through  $k$ ,  $A_1$  uao provided  $F_a$  ueo.

*Proof:*

Since the elements of  $A_1$  alternate they will fill  $A_1$  since the Kosaraju move takes precedence provided they cannot escape. By directionality (Fact 2) and Lemma 2 this cannot happen. □

*Lemma 4:* In steps 2 through  $k$ ,  $A_2$  emits ones uniformly provided  $F_a$  is a uao.

*Proof:*

$K$  rule takes precedence. □

*Fact 4:* The source is constant in steps 2 and 3.

*Lemma 5:* In steps 4 through  $k$ , SOURCE is ueo.

*Proof:*

By Lemma 4,  $A_2$  will be a uao. SOURCE emits from upper right hand corner. □

*Corollary 1:* (of Lemmas 3 & 4)  $F_a$  is a uo, through step  $k$ .

*Corollary 2:* (of Lemma 2)  $B_2$  is a ueo, through step  $k$ .

*Corollary 3:* (of all lemmata) 1 and 0 are constant through step  $k$ .

*Lemma 6:* After  $k$  steps (preamble) the configuration is:

*Proof:*

Apply lemmas and corollaries. □

*Remark:* The computation is "stable" hereafter until the interaction completes. The behavior is as follows:

- Source is ueo
- $A_2$  is uo
- $F$  is uo (by  $k$  moves)
- $B_1$  is a uo
- target is a uao.

We now argue the behavior of  $F$  and then describe iteration.

*Lemma 7:* As long as  $A_2$  is a ueo and  $B_1$  is a uao, then  $F$  is a uo until  $k$  moves.

*Proof:*

By Lemma 6 and hypotheses of lemma, we may consider only the local behavior which is initially:

with directionality

The transitions are (given  $A_2$  is uco and  $B_1$  uao)

step (odd)                      (even)                      (odd)

**Fact 5:** At step  $k$ , target contains  $l+1$  ones and source has emitted  $l-1$  ones.

**Definition:** An iteration is completed when target is filled.

**Remark:** The results thus far demonstrate that the 1's will stream uniformly into target until it fills. We are seeking to show that once target is filled, a new one is started without breaking cadence; and analogously for sources. Before the actual argument we first discuss the timing in anticipation of the complexity arguments later.

**Lemma 8:** Target requires  $4k-2$  steps to fill from its initial configuration.

**Proof:**

The initial configuration is 

1
---

A total of  $2k$  1's are required of which one is present. It takes 2 steps to each 1.

$$2(2k-1) = 4k-2 \quad \square$$

**Remark:** Note, initially 1 step is required to get in "phase."

**Lemma 9:** If  $B_1$  is uco, then on the step that target is filled, a new target is defined and in initial configuration.

**Proof:**

Step before fill                      fill                       $\square$

**Lemma 10:** "A new target is smoothly defined"

Finally, the final configuration is not reached until  $cn^2$  steps ( $c > 0$  constant).

**Proof:**

The conclusion begins after 2 iterations, where the first iteration contains the preamble steps. The state at conclusion is

The three transition rows will be filled in the conclusion.

$$\begin{aligned} \text{Total steps to conclusion} &= l(4k-2)+1 \\ &\quad \text{by Lemma 7} \\ &= 8l^2+2l+1 \end{aligned}$$

$$n = 16l^2+24l+9 \quad \square$$

#### 4. Other Rules

In this section we present two further rules and show (or rather sketch) that they both require  $cn^2$  time in the worst case to sort.

In the first set of rules we consider that the array is organized as a cylinder (see Figure 2).

Figure 2: The cylinder array.

One column is distinguished and is called the *data line*. The rules are then bubble if you can; otherwise, shift to the left if you can (just as before). In addition, we add a new rule:

A 1 can wrap around (see Figure 3), i.e., cross the data line going to the left provided the position  $\alpha$  is a 0.

Figure 3: New rule.

The rationale behind this rule is that it seemed to allow the array to break up large blocks of 1's that are packed to the left as in the Kosaraju counterexample. However, this is not the case:

**Theorem:** The cylinder scheme requires  $cn^2$  ( $c > 0$  constant) in worst case.

We will omit the proof of this theorem and remark only that it is based on the example

and shows that the time required is  $n^2-n+1$ .

Our third set of rules is one based on a set of interchange rules due to Floyd [1]. We assume that  $n$  is odd and we operate on the array as follows:

*Step 1:* Apply left (right) Floyd rules to odd (even) rows.

*Step 2:* Apply up Floyd rules to columns.

*Step 3:* Apply right (left) Floyd rules to odd (even) rows.

*Step 4:* Repeat step 2.

The right (left) Floyd rule is: a 1 can interchange with a 0 that is to its left (right).

The up version is defined in a similar manner.

Thus, the left Floyd on

0 1 0 1 0 1 1 1

is

1 0 1 0 1 0 1 1

and the right Floyd is

0 0 1 0 1 1 1 1.

Although these rules are less local than our previous ones, they suffer the same fate:

*Theorem:* The above set of rules sorts in time  $cn^2$  ( $c > 0$  constant) in worst case.

Again we omit the proof and just remark that it is based on the example
